(57) **ABSTRACT**

A method of detecting a signal in an optical receiver is described. The method includes converting a received optical signal to a digital electrical signal comprising a plurality of samples, applying a predetermined phase rotation to said samples to obtain amplitude and phase components of phase range adjusted sample values, and performing a first detection process based on the amplitude and phase components of the phase range adjusted sample values.

RECEIVER FOR OPTICAL TRANSMISSION SYSTEM

CROSS-REFERENCE TO RELATED APPLICATIONS

This application is a National stage of International Application No. PCT/EP2012/064596, filed Jul. 25, 2012, which claims priority to EP Application No. 12172268.0, filed Jun. 15, 2012, which are hereby incorporated by reference.

TECHNICAL FIELD

This invention relates to a receiver for an optical transmission system, and in particular to a receiver that is able to mitigate the effects of non linear distortion in the transmission medium, which might for example be a fibre, and to a method of signal detection in such a receiver.

BACKGROUND

Optical transmission systems, in particular optical fibre transmission systems, are widely used for sending signals over long distances. That is, electrical signals representing data are converted into optical signals, which are transmitted over the transmission medium (such as the optical fibre) to a receiver, where they are converted back to electrical signals. Signal detection processes are then performed in the receiver, in order to recreate as far as possible the data content of the original electrical signals. In order to achieve this recreation of the original data content, various signal detection techniques can be used, in order to compensate for the effects of distortion that occur in the transmission medium (such as the optical fibre).

It is known that linear distortion can be compensated to a large extent by adaptive linear equalizers, but there are also non-linear distortions, and it is more difficult to mitigate the effects of these. The document "Compensation of dispersion and nonlinear impairments using digital backpropagation", E. Ip and J. Kahn, J. Lightwave Technol. 26,3416-3425 (2008), describes a technique whereby the received digitized signal is back-propagated toward the transmission end by solving, in the digital domain, the Non Linear Schrodinger equation that describes propagation in the optical fibre. This technique is computationally very demanding, and has not provided wholly satisfactory results.

SUMMARY

According to the present invention, there is provided a method of detecting a signal in an optical receiver. According to the method, a received optical signal is converted to a digital electrical signal comprising a plurality of samples. A predetermined phase rotation is applied to said samples to obtain amplitude and phase components of phase range adjusted sample values. A first detection process is then performed based on the amplitude and phase components of the phase range adjusted sample values.

This has the advantage that, because some non-linearly distorted signals can be modelled with acceptable accuracy by Gaussian distributed correlated amplitude and phase components, the first detection process can produce accurate detection results.

In some embodiments, the received optical signal is converted to a digital electrical signal by converting the received optical signal to a digital electrical signal having in-phase and quadrature components, and the in-phase and

2

quadrature components are converted to amplitude and phase components before performing the first detection process.

In some embodiments, said predetermined phase rotation is applied to said samples before converting said in-phase and quadrature components to amplitude and phase components. An inverse of said predetermined phase rotation is then applied to said phase components such that the phase range adjusted sample values have phases within ranges suitable for said conversion.

This has the advantage that the conversion of the in-phase and quadrature components to amplitude and phase components then produces results that can be manipulated as required.

The predetermined phase rotation can be determined in a training process, and retrieved from a look up table, based on a phase of the respective sample.

In some embodiments, the first detection process is a Maximum Sequence Likelihood Estimation process, for example using a Viterbi algorithm.

In some embodiments, a second detection process is performed, based on said in-phase and quadrature components of the digital electrical signal. A detector output is then selected from outputs of the first and second detection processes, for example based on respective quality measurements of outputs of the first and second detection processes.

In some embodiments, the second detection process is a Maximum Sequence Likelihood Estimation process, for example using a Viterbi algorithm.

The optical receiver may be an optical fibre receiver.

According to other aspects of the invention, there are provided: a detector, for detecting a signal in an optical receiver, the detector comprising a processor adapted to operate in accordance with a method according to the first aspect; an optical receiver, comprising an optical front end and such a detector (80); and a computer readable medium, comprising computer readable code for performing the method according to the first aspect.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1 shows an optical transmission system.

FIG. 2 shows a receiver for use in a node of the optical transmission system of FIG. 1.

FIG. 3 shows a method of signal processing in a receiver.

FIG. 4 illustrates a first detector for use in the receiver of FIG. 2.

FIG. 5 illustrates in more detail a block of the receiver in the detector of FIG. 4.

FIGS. 6(a) and 6(b) illustrate two forms of equalizer for use in the receiver of FIG. 2.

FIG. 7 illustrates an alternative detector.

FIG. 8 illustrates a second detector for use in the receiver of FIG. 2.

FIGS. 9(a) and 9(b) illustrate two further forms of equalizer for use in the receiver of FIG. 2.

FIGS. 10(a) and 10(b) are results of simulations using different receivers.

DETAILED DESCRIPTION

FIG. 1 is a schematic illustration of a part of an optical transmission system. In this embodiment, the optical transmission system is a fibre optic transmission system. FIG. 1 shows three network nodes 10, 20, 30, connected by optical fibre links 2, 4. A first node 10 includes a transmitter 12. A second node 20 has a receiver 21 and a transmitter 22. A

3

third node **30** has a receiver **31**, which includes an equalizer **32**. It will be appreciated that an optical transmission system will be more complex than this, but FIG. 1 shows only those elements of the system that are essential for an understanding of the present invention.

In use, an electrical signal representing data is converted into optical signals in the transmitter **22**, and the optical signals are transmitted over the optical fibre **4** to the receiver **31**, where they are converted back to electrical signals. Signal detection processes are then performed in the receiver, in order to recreate as far as possible the data content of the original electrical signals.

FIG. 2 shows in more detail the form of the receiver **31**. The receiver **31** includes a coherent optical front end block **40**. In this embodiment, the block **40** is configured to produce Cartesian components of the received signal in two polarizations. Thus, a received optical signal is applied to a polarization splitter **42**, which splits the received signal into the two polarization components. An output of a local laser **44** is applied to a second polarization splitter **46**, and is mixed with the polarization components of the incoming signal. The four resulting mixed optical output signals are applied to four pairs of photodetectors **51**, **52**, **53**, **54**. The photodetectors **51**, **52**, **53**, **54** generate analog electrical signals, which are applied to respective analog-digital converters **55**, **56**, **57**, **58**, which generate digital electrical signals.

The digital electrical signals are applied to the equalizer **32**, which can advantageously take the form of a Digital Signal Processor (DSP). The DSP will typically take the form of a single integrated circuit, provided with suitable instructions for performing the functions of one or more of the embodiments described herein.

In this illustrated embodiment, the equalizer **32** includes a linear equalizer **60**, which can take the form of a conventional equalizer, for example including a Finite Impulse Response (FIR) filter and/or an Infinite Impulse Response (IIR) filter, although it will be understood that this can be omitted if the only concern is to mitigate the effects of non-linear distortion.

In this illustrated embodiment, the equalizer **32** also includes a backpropagation block **70**, which can include at least one cascade of a linear equalization element (LEE) **71** and a non-linear equalization element (NLEE) **72**, as described in the document WO2010/094339. Again, it will be understood that the backpropagation block **70** can be omitted if the effects of non-linear distortion can be sufficiently mitigated without it.

The equalizer **32** also includes a detector **80**. The inventors have surprisingly discovered and subsequently recognised that, in certain circumstances, particularly in the case of compensated optical fibre links such as those using non-zero dispersion fibre (NZDF), the non-linearly distorted signals can be modelled with acceptable accuracy by Gaussian distributed correlated amplitude and phase components (that is, they are approximately Gaussian in polar coordinates), while they show Gaussian In-phase and Quadrature (I/Q) components (that is Gaussian in Cartesian coordinates) in uncompensated links or in links with high dispersive fiber such as single mode fibre (SMF).

FIG. 3 is a flow chart, illustrating a method of receiving signals, in the receiver **31**. Thus, in step **100**, the optical signal is received at the front-end **40**. In step **102**, the optical signal is converted to an electrical signal in the photodetectors **51**, **52**, **53**, **54**. In step **104**, the electrical signals are sampled, and converted to digital signals.

4

In step **106**, a linear equalization may be performed by the linear equalizer **60**. In step **108**, back propagation may be performed by the backpropagation block **70**.

In step **110**, a detection process is performed. As mentioned above, the described embodiment proceeds from the recognition that the non-linearly distorted signals have Gaussian distributed correlated amplitude and phase components, and so the detection is performed using the amplitude and phase components, as described in more detail below. In step **112**, the detected signals are output.

FIG. 4 shows the form of the detector **80**, where it takes the form of a polar Gaussian detector block **116**, specifically a maximum sequence likelihood detector (MLSD) operating only on polar metrics for a single polarization.

In this case, it is assumed that the front-end **40** generates samples in Cartesian form, that is, it generates in-phase and quadrature components of each sample. Thus, in order to act on the polar components, the Cartesian components need to be converted to polar form.

However a simple evaluation of the phase leads to incorrect signal estimates. The inventors have appreciated that this problem arises from the limited range for the phase extraction function (e.g. $-\pi$ to π in one common implementation of the phase extraction function using the arctan relationship between the Cartesian components). Specifically, samples that have very similar phases can appear to be at the two extreme ends of this range, with the result that taking the average phase will give an incorrect result.

To obtain the correct Gaussian parameters the phase of the samples needs to be continuously monitored and centered. As described in more detail below, this is achieved by rotating incoming samples by a specific phase value, which is computed during a training phase and stored in a look-up table.

Thus, during a first training phase, Cartesian samples representing a suitable sequence of training symbols are passed to a first input **118** of the detector. The received samples are passed to a sequence average estimation (SAE) block **120**, which determines the average of the samples of the training sequence. Then, a phase extractor **122** computes the phase for the averaged value and the obtained phases are stored in a phase range adaptor look up table (PRA LUT) **124**. As shown in FIG. 4, the PRA LUT **124** has M^L rows, where L is the channel memory, and M is the symbol cardinality, with each row containing the calculated phase value for each combination of symbol identifier and state identifier of a received sample.

After the first training phase is complete, Cartesian samples representing a second training sequence are passed to a second input **130** of the detector. The received samples are then passed to a phase range adaptor (PRA) block **132**, which adjusts the phase of the received samples.

FIG. 5 shows in more detail the form of the PRA block **132**. Specifically, a received sample value y_{pol} in Cartesian form is passed to a rotator **134**. The transmitted symbol is known, as it is part of the training sequence, and so this allows the appropriate row in the PRA-LUT **124** to be accessed, and the stored phase value ω is retrieved.

The rotator then rotates the sample value y_{pol} by the inverse of the stored phase value ω , by multiplying y_{pol} by $e^{-i\omega}$ to obtain a rotated sample value z . The rotated sample value z is then passed to a Cartesian-to-polar converter block **136**, which obtains polar components, namely the amplitude ρ and phase θ , in a conventional manner from the Cartesian components. The phase θ therefore lies in the range used by the phase extraction function (e.g. $[-\pi, \pi]$).

The calculated phase θ of the rotated sample value z is then passed to a correction block **138**, where the stored phase value ω is added to the calculated phase θ to obtain a phase range adapted phase value $\theta_{PRA} = \theta + \omega$. This effectively applies a derotation that is equal and opposite to that applied by the rotator **134**, and so the phase range adapted phase value θ_{PRA} is equal to the phase of the sample value y_{pol} but is established in the adapted range $[(-\pi + \omega), (\pi + \omega)]$. Thus, this phase range adapted phase value is in a new range, allowing the average phase value of the samples to be taken accurately.

The amplitude ρ and the phase range adapted phase value θ_{PRA} are then passed to a Signal Average and Covariance Estimator block (SACME) **140**, which operates as in a conventional Viterbi decoder to populate a second look-up table **142**. As shown in FIG. 4, this look-up table **142** has a row for each symbol and state combination, and stores values of the signal amplitude average, the phase average and the covariance matrix values for each combination.

After the training has been completed, the detection step is performed by passing incoming samples to a third input **144** of the detector. The received samples are then passed to a phase range adapter (PRA) block **146**, which operates in exactly the same manner as the phase range adapter (PRA) block **132** shown in FIG. 4, and thus adjusts the phase of the received samples, based on the content of the PRA-LUT **124**. The effect of this phase rotation is that the phase range of the symbols can be centered, and so the average phase of the symbols can be calculated correctly.

The received samples, in phase adjusted polar form, are then passed to a Viterbi decoder **148**. Thus, in this case, the Viterbi algorithm operates with metrics based on the polar coordinates. The detector **148** then generates output values that can be passed to a further block of the receiver.

In addition, the LUT **142** can be updated during this detection step, assuming the decisions on the symbols are correct.

Although this embodiment is illustrated with reference to the case where the detector uses a Viterbi decoder block **148**, any suitable detection strategy can be used. In particular any Maximum Likelihood Sequence Detection algorithm can be used. The Viterbi decoder block **148** can be replaced by an equalizer.

Embodiments have been described so far with reference to a receiver that is suitable for use in a transmission system in which the signals are transmitted with a single polarization. However, the same principle can be used in a transmission system using polarization multiplexed transmission, in which case signals are transmitted with two (or more) polarizations.

FIG. 6 shows two possible forms of the equalizer **32** that can be used in the case of polarization multiplexed transmissions. In FIG. 6, the equalizer **32** includes a digital linear equalizer **60** and a detector **80**. As in FIG. 2, a backpropagation block **70** can be included if required.

FIG. 6(a) shows an equalizer **32** in which the digital linear equalizer **60** generates two parallel streams of samples (Pol 1 and Pol 2), representing the samples sent with the two polarizations, with these streams being processed independently. That is, the detector **80** includes two polar Gaussian detector blocks **160**, **162**, each having the same general form as the polar Gaussian detector block **116** shown in FIG. 4, and each having a respective second look-up table **164**, **166**.

FIG. 6(b) shows an alternative equalizer **32** in which the digital linear equalizer **60** again generates two parallel streams of samples (Pol 1 and Pol 2), representing the samples sent with the two polarizations, and these streams

are processed jointly. That is, the detector **80** includes one polar Gaussian detector block **170**, having the same general form as the polar Gaussian detector block **116** shown in FIG. 4, but operating with joint metrics, and having a single second look-up table **172**.

As described previously, the polar Gaussian detection scheme works best in compensated links with low dispersion fiber. However, there remain network scenarios in which detection based on Cartesian Gaussian coordinates produces better results.

FIG. 7 therefore illustrates a detector suitable for operating on Cartesian Gaussian components of samples.

During a first training phase, Cartesian samples representing a suitable sequence of training symbols are passed to a first input **180** of the detector. The Cartesian components are then passed to a Signal Average and Covariance Estimator block (SACME) **182**, which operates as in a conventional Viterbi decoder to populate a look-up table **184**. As shown in FIG. 7, this look-up table **184** has a row for each symbol and state combination, and stores values of the signal average in-phase component, the average quadrature component and the covariance for each combination.

After the training has been completed, the detection step is performed by passing incoming samples to a second input **186** of the detector. The received samples are then passed to a Viterbi decoder **188**. The detector **188** then generates output values that can be passed to a further block of the receiver. It is noted that the Cartesian Gaussian metrics also accounts for correlation between the terms and is different from a scheme based on complex signal processing, using Euclidean Distance metrics.

Again, although this embodiment is illustrated with reference to the case where the detector uses a Viterbi decoder block **188**, any suitable detection strategy can be used. In particular any Maximum Likelihood Sequence Detection algorithm can be used. The Viterbi decoder block **188** can be replaced by an equalizer.

FIG. 8 shows a combined detector **200**, that can use both Cartesian and Polar strategies, selecting the best one based on performance measurements.

Thus, during a first training phase of the detector **200**, Cartesian samples representing a suitable sequence of training symbols are passed to a first input **202** of the detector. The received samples are passed to a sequence average estimation (SAE) block **204**, which determines the average of the samples of the training sequence). Then, a phase extractor **206** computes the phase for the averaged value and the obtained phases are stored in a phase range adaptor look up table (PRA LUT) **208**, as described with reference to FIG. 4.

After the first training phase is complete, Cartesian samples of a second training sequence are passed to a second input **210** of the detector. The received samples are then passed to a selector **212**. The selector **212** can be controlled so that the detector **200** is trained in both Cartesian and Polar strategies.

When the selector **212** is set such that training in the polar strategy is being performed, the received samples are passed to a phase range adapter (PRA) block **214**, which operates in the same way as the PRA block **132** shown in FIG. 5, in that it adjusts the phase of the received samples, and generates an amplitude value and a phase range adapted phase value, which are then passed to a Signal Average and Covariance Estimator block (SACME) **216**, which operates as in a conventional Viterbi decoder to populate a second look-up table **218**.

When the selector **212** is set such that training in the Cartesian strategy is being performed, the Cartesian components of the received samples are passed direct to the Signal Average and Covariance Estimator block (SACME) **216**, which operates as in a conventional Viterbi decoder to populate the look-up table **218**.

After the training has been completed, the detection step is performed by passing incoming samples to a third input **220** of the detector. The received samples are then passed to a second selector **222**.

The second selector **222** is controlled by a control block **224**, which determines whether the detector should operate using the Cartesian or Polar strategy. In this illustrated embodiment, the output signal of the detector at the output point **226** is also passed to the control block **224**, which determines a quality measurement of the output signal. For example, the control block **224** can determine whether the bit error rate (BER) of the output signal is above or below a certain threshold value, and can switch to select the other strategy if the BER of the output signal is above the threshold value. As another example, the control block **224** can control the second selector **222** to switch between the Cartesian and Polar strategies, and can then control the second selector **222** to select the strategy that produces the lower BER. The control block **224** can also allow external control, so that a user and/or an external controller can determine whether the detector should operate using the Cartesian or Polar strategy.

When the second selector **222** is set such that the polar detection strategy is being performed, the received samples are passed to a phase range adapter (PRA) block **228**, which operates in exactly the same manner as the phase range adapter (PRA) block **132** shown in FIG. 4, and thus adjusts the phase of the received samples, based on the content of the PRA-LUT **208**.

The received samples, in phase adjusted polar form, are then passed to a Viterbi decoder **230**. Thus, in this case, the Viterbi algorithm operates with metrics based on the polar coordinates. The detector **230** then generates output values that can be passed to the output **226**, and then to a further block of the receiver.

In addition, the second LUT **218** can be updated during this detection step, assuming the decisions on the symbols are correct.

When the second selector **222** is set such that the Cartesian detection strategy is being performed, the detection step is performed by passing incoming samples to the Viterbi decoder **230**. The detector **230** then generates output values that can be passed to the output **226**, and then to a further block of the receiver. As before, the Cartesian Gaussian metrics also accounts for correlation between the terms and is different from a scheme based on complex signal processing, using Euclidean Distance metrics.

Again, although this embodiment is illustrated with reference to the case where the detector uses a Viterbi decoder block **230**, any suitable detection strategy can be used. In particular any Maximum Likelihood Sequence Detection algorithm can be used. The Viterbi decoder block **230** can be replaced by an equalizer.

Thus, the detector can select between the two strategies, based on BER feedback, or based on a preset value. This provides additional flexibility, when required by the network scenario to be addressed.

Embodiments have been described so far with reference to a combined detector receiver that is suitable for use in a transmission system in which the signals are transmitted with a single polarization. However, the same principle can

be used in a transmission system using polarization multiplexed transmission, in which case signals are transmitted with two (or more) polarizations.

FIG. 9 shows two possible forms of the equalizer **32** that can be used in the case of polarization multiplexed transmissions. In FIG. 9, the equalizer **32** includes a digital linear equalizer **60** and a detector **80**. As in FIG. 2, a backpropagation block **70** can be included if required.

FIG. 9(a) shows an equalizer **32** in which the digital linear equalizer **60** generates two parallel streams of samples (Pol 1 and Pol 2), representing the samples sent with the two polarizations, with these streams being processed independently. That is, the detector **80** includes two combined detector blocks **200**, each having the same general form as the combined detector **200** shown in FIG. 8, and each having a respective second look-up table **218**.

FIG. 9(b) shows an alternative equalizer **32** in which the digital linear equalizer **60** again generates two parallel streams of samples (Pol 1 and Pol 2), representing the samples sent with the two polarizations, and these streams are processed jointly. That is, the detector **80** includes one combined detector block **200**, having the same general form as the combined detector block **200** shown in FIG. 8, but operating with joint metrics, and having a single second look-up table **218**.

FIG. 10 illustrates the results of using the method described herein, based on a simulation considering single channel transmission and single polarization. A 50 Gb/s NRZ-DQPSK transmitted signal was generated by a nested Mach-Zehnder modulator with 20 GHz bandwidth and filtered by a 4th-order Gaussian bandpass filter with 45 GHz bandwidth. The received signal was filtered by a 4th-order Gaussian bandpass filter with 40 GHz bandwidth and processed according to different strategies, with 2 samples per symbol. The Viterbi Algorithm (VA) with ED (Euclidean Distance), CG (Cartesian Gaussian), or PG (Polar Gaussian) metrics is implemented with 16 states (nonlinear ISI limited to 2 symbols). For each state and symbol, the required conditional expectation and covariance matrix (for CG and PG only) are estimated and stored in a look-up table by using a suitable training sequence and assuming that samples spaced more than $1/R$ are uncorrelated. FIG. 10 compares the performances of these detection methods, in terms of bit error rate (BER) versus launch power, for a 10x130 km link of fiber.

FIG. 10(a) shows the results when using G655 non-zero dispersion fibre (NZDF), the nonlinear inter-symbol interference (ISI) induced by dispersion and nonlinearity is limited to a few symbols and can be handled by the 16-state VA. It can be seen that the polar Gaussian (PG) metric better accounts for nonlinear phase noise and therefore produces better results (indicated by the line **230**) than those produced by the Cartesian Gaussian (CG) metric (indicated by the line **232**) and the Euclidean distance metric (indicated by the line **234**) and outperforms the backpropagation (BP) algorithm (indicated by the line **236**).

FIG. 10(b) shows the results when using G652 single mode fibre (SMF), where dispersion is higher, and nonlinear ISI depends on a high number of symbols and dominates the performance. In this case, FIG. 10(b) shows that increasing the number of states of the Viterbi processor to 256 produces better results. It can also be seen that, using the 256-state VA, the Cartesian Gaussian (CG) metric produces better results (indicated by the line **240**) than those produced by the polar Gaussian (PG) metric (indicated by the line **242**) and

the Euclidean distance metric (indicated by the line 244) and also outperforms the backpropagation (BP) algorithm (indicated by the line 246).

This suggests that the effectiveness of the Cartesian Gaussian scheme described above for high cumulative dispersion links may require VA states to account for a longer nonlinear ISI. As an alternative, or additionally, an initial backpropagation block can be used to partially absorb the long nonlinear interaction due to high dispersion, either when using non-compensated G655 non-zero dispersion fibre or when using non-compensated G652 single mode fibre.

There are thus described a receiver that is able to mitigate the effects of non linear distortion in the fibre, and a method of signal detection in such a receiver.

References to processors, hardware, processing hardware or circuitry can encompass any kind of logic or analog circuitry, integrated to any degree, and not limited to general purpose processors, digital signal processors, ASICs, FPGAs, discrete components or logic and so on. References to a processor are intended to encompass implementations using multiple processors which may be integrated together, or co-located in the same node or distributed at different locations for example. References to a processor also encompass implementations including one or more optical devices and circuits, including photodetectors and associated analog to digital converters, and integrated circuits containing such devices.

The functionality of circuits or circuitry described herein can be implemented in hardware, software executed by a processing apparatus, or by a combination of hardware and software. The processing apparatus can comprise a computer, a processor, a state machine, a logic array or any other suitable processing apparatus. The processing apparatus can be a general-purpose processor which executes software to cause the general-purpose processor to perform the required tasks, or the processing apparatus can be dedicated to perform the required functions.

Embodiments can have programs in the form of computer readable code i.e. machine-readable instructions (software) which, when executed by a processor, perform any of the described methods. The programs may be stored on an electronic memory device, hard disk, optical disk or other machine-readable storage medium or non-transitory medium. The programs can be downloaded to the storage medium via a network connection.

The invention claimed is:

1. A method of detecting a signal in an optical receiver, the method comprising:

converting a received optical signal to a digital electrical signal comprising a plurality of samples having in-phase and quadrature components;
applying a predetermined phase rotation to said samples;
converting the in-phase and quadrature components to amplitude and phase components;
applying an inverse of the predetermined phase rotation to the phase components such that phase range adjusted sample values have phases within ranges suitable for detection: and
performing a first detection process based on the amplitude and phase components of the phase range adjusted sample values.

2. The method as claimed in claim 1, wherein the predetermined phase rotation is determined in a training process.

3. The method as claimed in claim 1, further comprising retrieving values for the predetermined phase rotation from a look up table, based on a phase of the respective sample.

4. The method as claimed in claim 1, wherein the first detection process is a Maximum Sequence Likelihood Estimation process.

5. The method as claimed in claim 1, further comprising: performing a second detection process based on the in-phase and quadrature components of the digital electrical signal; and selecting a detector output from outputs of the first and second detection processes.

6. The method as claimed in claim 5, wherein the second detection process is a Maximum Sequence Likelihood Estimation process.

7. The method as claimed in claim 5, further comprising: selecting the detector output based on respective quality measurements of outputs of the first and second detection processes.

8. The method as claimed in claim 1, wherein the optical receiver is an optical fibre receiver.

9. A detector for detecting an optical signal, the detector comprising a processor that is operative to:

convert a received optical signal to a digital electrical signal comprising a plurality of samples having in-phase and quadrature components;

apply a predetermined phase rotation to said samples;
convert the in-phase and quadrature components to amplitude and phase components;

apply an inverse of the predetermined phase rotation to the phase components such that phase range adjusted sample values have phases within ranges suitable for detection: and

perform a first detection process based on the amplitude and phase components of the phase range adjusted sample values.

10. The detector as claimed in claim 9, wherein the detector is included in an optical receiver, wherein the optical receiver comprises an optical front end.

11. The detector as claimed in claim 10, wherein the detector is connected to a linear equalizer for receiving signals from the optical front end.

12. The detector as claimed in claim 10, wherein the detector is connected to a backpropagation block.

13. The detector as claimed in claim 9, wherein the predetermined phase rotation is determined in a training process.

14. The detector as claimed in claim 9, wherein the processor is further operative to retrieve values for the predetermined phase rotation from a look up table, based on a phase of the respective sample.

15. The detector as claimed in claim 9, wherein the first detection process is a Maximum Sequence Likelihood Estimation process.

16. The detector as claimed in claim 9, wherein the processor is further operative to:

perform a second detection process based on said in-phase and quadrature components of the digital electrical signal; and

select a detector output from outputs of the first and second detection processes.

17. The detector as claimed in claim 16, wherein the second detection process is a Maximum Sequence Likelihood Estimation process.

18. The detector as claimed in claim 16, wherein the processor is further operative to:

select the detector output based on respective quality measurements of outputs of the first and second detection processes.

11

19. The detector as claimed in claim 9, wherein the optical receiver is an optical fibre receiver.

20. A non-transitory computer readable storage medium having instructions stored therein, wherein the instructions, when executed by a processor of an optical device, causes the processor to perform operations comprising:

converting a received optical signal to a digital electrical signal comprising a plurality of samples having in-phase and quadrature components;

applying a predetermined phase rotation to said samples;

converting the in-phase and quadrature components to amplitude and phase components;

applying an inverse of the predetermined phase rotation to the phase components such that phase range adjusted sample values have phases within ranges suitable for detection; and

performing a first detection process based on the amplitude and phase components of the phase range adjusted sample values.

21. The non-transitory computer readable storage medium as claimed in claim 20, wherein the predetermined phase rotation is determined in a training process.

22. The non-transitory computer readable storage medium as claimed in claim 20, the instructions cause the processor to perform further operations comprising retrieving values

12

for the predetermined phase rotation from a look up table, based on a phase of the respective sample.

23. The non-transitory computer readable storage medium as claimed in claim 20, wherein the first detection process is a Maximum Sequence Likelihood Estimation process.

24. The non-transitory computer readable storage medium as claimed in claim 20, the instructions cause the processor to perform further operations comprising:

performing a second detection process based on the in-phase and quadrature components of the digital electrical signal; and

selecting a detector output from outputs of the first and second detection processes.

25. The non-transitory computer readable storage medium as claimed in claim 24, wherein the second detection process is a Maximum Sequence Likelihood Estimation process.

26. The non-transitory computer readable storage medium as claimed in claim 24, the instructions cause the processor to perform further operations comprising:

selecting the detector output based on respective quality measurements of outputs of the first and second detection processes.

27. The non-transitory computer readable storage medium as claimed in claim 20, wherein the optical receiver is an optical fibre receiver.
